Abstract
This paper describes studies focusing on how gender and grouping affects performance and attitudes of children playing a puzzle solving game called The Incredible Machine. We found that children playing together on one machine solved significantly more puzzles than children playing alone on one machine. Female/Female pairs playing together on one machine, on average, completed significantly more puzzles than Female/Female pairs playing side-by-side on two computers. In addition, the level of motivation to continue playing the game was affected by the opportunity to play with a partner, and success in the game.

1. Introduction
Children naturally tend to gather in groups around computers and video games. This is common in arcades, living rooms, and classrooms, but was also overwhelmingly evident during a research study of children playing electronic games conducted at an interactive science museum, Science World, in 1993. This paper describes follow-on studies focusing on how gender and grouping affects performance and attitudes of children playing a puzzle solving game.

The Science World 1993 study was the first research undertaken by the Electronic Games for Education in Math and Science (E-GEMS) group, an ongoing collaborative effort among scientists, mathematicians, educators, professional game developers, classroom teachers, and children. The goal of E-GEMS is to motivate children to learn and explore mathematical and scientific concepts through the use of electronic games. E-GEMS research includes focused studies on specific issues [7], long term qualitative investigations [9], development and evaluation of prototypes, and design of commercial products [2].

Science World is an interactive science museum where children and adults explore scientific concepts through a variety of hands-on activities. In July 1993 E-GEMS researchers set up an exhibit at Science World to observe children as they interacted with video games and computer games. During the two month exhibit, over ten thousand children spent time in the exhibit and several hundred children were interviewed by researchers. Two strong themes that emerged from our observations were the popularity of collaborative play and differences in gender preferences and playing styles. Gender differences are reported in detail elsewhere [6,10]. This paper presents the outcomes of a two-phase further investigation of collaborative play conducted in a school classroom in January 1994 and at Science World in the summer of 1994.

Researchers have noted positive benefits from small group interactions around computers in the classroom [4,11,15]. Some studies include comparisons between individual, cooperative, and competitive groupings [8,3]. In our study we chose to focus on the playing configuration rather than explicitly forcing children into competitive or collaborative playing modes. Children were placed in one of three physical set-ups:

Solo Play: one child alone on one machine
Parallel Play: two children side-by-side on two machines
Integrated Play: two children together on a single machine

The game chosen, The Incredible Machine (TIM), is a problem solving game in which players assemble Rube Goldberg style machines out of a collection of parts to solve challenges posed by the game. Typical challenges include building a machine to shoot a basketball into a hoop and trapping Mort the Mouse in his cage. The parts include many used in everyday life (e.g. gears, pulleys, ropes, ramps and levers) along with a host of characters and entertaining objects (e.g. cats, mice, balloons, various types of balls, and trampolines). During the Science World 1993 study, re-
searchers frequently observed collaboration on TIM by
groups of children, including groups of children who
had never previously met.

At Science World 1993, many groups of children
played TIM for extended periods of time. Some
groups passed control of the mouse back and forth
while other groups had one person perform the group's
suggestions. Often, the children in the group were ac-
tive participants in sharing ideas and directing actions
within the game. The children who played TIM in
groups appeared to play for longer periods of time and
appeared better able to solve the puzzles. These obser-
vations led us to hypothesize that children playing TIM
in pairs would, on average, complete more puzzles
during a fixed period of time, and would choose to play
longer.

2. TIM Study

2.1. Phase I: Kerrisdale School, 1994

The first phase of the current TIM study was conducted
at Kerrisdale Elementary School, a public elementary
school in an upper-middle class neighborhood of Van-
couver, British Columbia, Canada. The participants
were 104 children (52 girls and 52 boys) between the
ages of 9 and 12 who had not previously played TIM.
Students were arbitrarily placed into one of the three
experimental conditions described above, namely Solo
Play, Parallel Play and Integrated Play. For the two-
player conditions, the students were randomly assigned
a partner corresponding to a particular sex-dyad. The
gender groupings were: Female/Female, Male/Male,
and Female/Male.

The setting was an empty classroom equipped
with either one or two IBM-compatible computers, de-
pending on the experimental condition. The total
length of each session was forty minutes. The children
were welcomed and given a brief introduction to the
project and the environment. Next, the children were
asked to try to complete the first three puzzles in the
game and told that they were allowed to play for as
long as they desired up to a maximum of thirty min-
utes. The children were given no directions on how to
play to game. The game manual was placed on the
table beside the computer and the children were told
that it contained information about the game and that
they could look at it if they wished. They were en-
couraged to try to work out any problems they might
have amongst themselves. The children were also told
that when they finished playing, they could come into
another section of the room for a snack. Once in the
snack room, the children completed a questionnaire
and engaged in casual discussion until their forty min-
utes was completed. Following this, they returned to
their classes.

The factors investigated in this study were
achievement in the game (the total number of puzzles
completed by each student), and motivation to play the
game (whether or not the children played the game for
the full thirty minute period allowed). Qualitative obser-
vations were also gathered concerning the cooperative
play of the children and the group dynamics for the
Parallel Play and Integrated Play conditions.

Table 1 shows the mean number of puzzles com-
pleted during each of the experimental conditions.
Both girls and boys solved more puzzles in the Inte-
grated Play condition than in the Solo Play condition,
although the difference was not significant due to the
small sample size.

The result for the Parallel Play condition was de-
pendent on gender. Girls solved, on average, fewer
puzzles in the Parallel Play condition than in the Solo
condition. In addition, girls in the Integrated Play con-
dition solved significantly more puzzles than girls in the
Parallel Play condition, with p<.05.

These results indicate that children's success when
playing with a partner may depend on the children’s
playing configuration and gender groupings. We did
not observe any effect on motivation since only five
children left before the thirty minute session was over.

2.2. Phase II: Science World, 1994

Because of the intriguing differences observed in Phase
I for achievement by girls in the Parallel Play and Inte-
grated Play conditions, we decided to repeat the study

with a larger sample size at Science World during the summer of 1994.

This phase of the research project used 331 children (247 girls and 84 boys) between the ages of 9 and 13; the disproportionate number of girls was deliberate because of the wide variation in results for girls observed during the first phase. The children who participated were visitors to Science World who volunteered to take part in the study. As before, none of the subjects had previously played the computer game TIM. Students were randomly chosen to play either alone or with a partner in one of the three experimental conditions. This time partners were chosen corresponding to one of two sex dyads: Female/Female or Male/Male. No mixed gender pairs were used.

The Research Lab at Science World contained four Macintosh LCIII computers set up so that four sessions could run simultaneously. The procedure for running each session was identical to that in Phase I, except that no snacks or questionnaires were involved. When the children finished playing, they left the exhibit and continued exploring Science World. The factors measured for this study were the same as in Phase I, namely achievement and motivation.

The average number of puzzles solved in each of the experimental conditions in Phase II are shown in Table 2. In Phase II, gender (female and male) and experimental condition (Solo Play, Parallel Play, and Integrated Play) had a statistically significant effect on the number of puzzles solved in the game, with p<.001 and p<.03 respectively.

The results from this study validate the trend observed in Phase I that girls and boys solved more puzzles playing together on one machine in the Integrated Play condition than playing by themselves in the Solo Play condition, with p<.05. In addition, the discrepancies observed in the Parallel Play condition were also repeated, i.e. girls solved statistically fewer puzzles in the Parallel Play condition than girls playing in the Integrated Play condition, with p<.06. Also, as observed in Phase I, girls in the Parallel Play condition solved on average fewer puzzles than girls in the Solo Play condition. On the other hand, boys solved more puzzles on average in the Parallel Play condition than in the Solo Play condition but fewer puzzles than in the Integrated Play condition although these differences was not statistically significant.

These results support previous reports in [1,3,13] demonstrating the advantages of small groups sharing a single computer. This seems especially true for girls, given that girls playing together on one machine solved significantly more puzzles than girls playing side-by-side on two machines.

The increased number of puzzles solved in the Integrated conditions for both girls and boys could be attributed to the necessary interaction that occurs while working together on one machine. This resulted in more verbal interaction in the Integrated Play condition than in the Parallel Play condition. This observation of increased verbal interaction during collaborative work on one machine is supported by another study [13] in which children playing together on one machine had more verbal interactions than children playing side-by-side on two machines. Elaboration, the discussion of and expanding on ideas, is recognized by many researchers as one of the underlying cognitive explanations of the benefits of cooperative learning [12].

Gender differences in achievement were significant in Phase II in contrast to Phase I. Girls solved significantly fewer puzzles in all conditions than boys, with p<.001. This result could be explained by many factors including differences in the environment, the selection process, and the type of platform and interaction style used. Phase I took place in an empty room in a school, during school hours. Phase II was in a science museum with many people wandering around the exhibit throughout the session. In addition, Phase II took place during summer break, leading to differences in the selection process. In Phase I almost all the children in eligible classes chose to participate since it was viewed as a desirable break from their regular school day. At Science World the children who took part gave up time that they could have spent at other highly attractive exhibits. The interface used in TIM also differed slightly between the phases because of the use of different computer platforms. The IBM-compatible implementation of TIM uses a point-and-click style of interface whereas the Macintosh implementation in Phase II uses a drag-and-drop style. A subsequent study of girls using both these interfaces showed a slight difference in the average number of puzzles solved [5]. In this study girls using the point-and-click interface on the IBM-compatible computer solved more puzzles than girls using the drag-and-drop interface on the Macintosh computer.

Phase II also demonstrated that playing configuration has a significant effect on motivation as measured by the number of children who stayed and played for the full thirty minute session. The percentages of children who left early are shown in Table 3. A higher
percentage of children left during the Solo Play condition than for the Parallel and Integrated Play condition. In addition, fewer girls left during the Integrated Play condition than in the Parallel Play condition. This result might be explained by two factors: success in the game and whether or not the child played with a partner. Success in the game seemed critical since of the 54 children who left early, all but three left before solving any puzzles. The presence of a partner may also have contributed to staying for the full thirty minute session, since a similar percentage of girls in the Solo Play and Parallel Play conditions could not solve any puzzles, 58% and 58.7% respectively, but a higher percentage of girls in the Solo Play condition left early.

3. Conclusions and Future Work

This study provides a basis for several directions of future research. Although much has been done in the area of computer-supported cooperative learning, further examination of the effect of technology is needed.

Previous literature of cooperative learning on computer tasks emphasizes how the teacher can structure cooperative tasks and group compositions to maximize academic and social benefits using existing technology. It is important to investigate whether some of the benefits of cooperative learning may be enhanced by changes in the computer hardware, the software, or the choice of user interfaces. Especially intriguing is the opportunity to adapt Computer-Supported Cooperative Work (CSCW) inspired multi-person interfaces to educational software. There is also a need for further research in multi-input systems and other shared-screen issues.

Although students in this study enjoyed to work with friends, they sometimes had difficulty sharing the input device. In a later study, the addition of a second mouse to TIM was shown to have a positive effect on achievement for children collaborating on one machine [7]. A system that allows children to work together as well as maintaining the ability for individual exploration may be an important advance in cooperative learning with computers.

The results of this study suggest that grouping children around one computer can positively affect performance as compared to children playing alone on one machine. In the case of Female/Female groupings, working together on one machine can have a significant benefit over working side-by-side on two machines. These results, combined with the extensively researched social benefits of cooperative learning, demonstrate a need to continue research and development in this direction.
